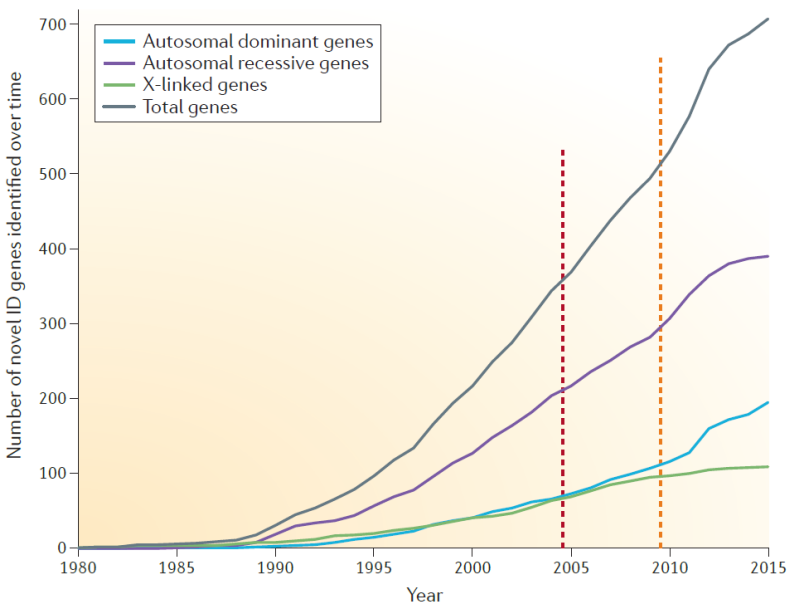
Rare Germline Mutations



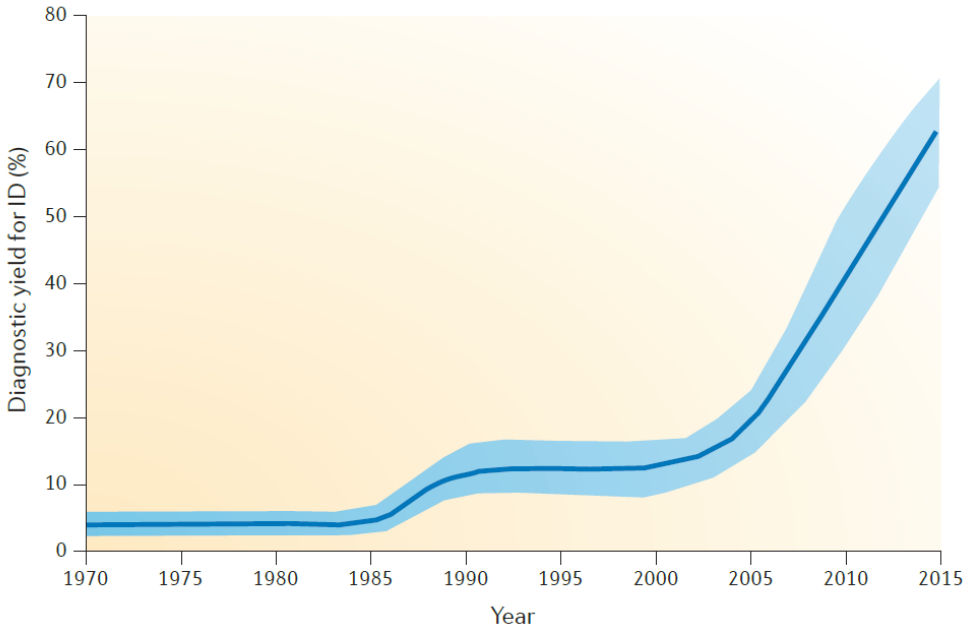


Figure 2 | **Diagnostic yield for ID over time.** Graphical overview of the diagnostic yield for moderate to severe intellectual disability (ID) (excluding Down syndrome, which represents 6–8% of all ID) over time. Solid line indicates the mean of published studies, and the shaded background indicates the lower and upper boundaries of reported diagnostic yields. In the 1970s, conventional karyotyping became a routine diagnostic test and provided a conclusive diagnosis in 3–6.5% of ID cases. The

Insufficient Evidence for "Autism-Specific" Genes

Scott M. Myers,[1,*] Thomas D. Challman,[1] Raphael Bernier,[2] Thomas Bourgeron,[3] Wendy K. Chung,[4,5] John N. Constantino,[6,7] Evan E. Eichler,[8] Sebastien Jacquemont,[9] David T. Miller,[10] Kevin J. Mitchell,[11,12] Huda Y. Zoghbi,[13,14,15,16,17] Christa Lese Martin,[1] and David H. Ledbetter[1,*]

Despite evidence that deleterious variants in the same genes are implicated across multiple neurodevelopmental and neuropsychiatric disorders, there has been considerable interest in identifying genes that, when mutated, confer risk that is largely specific for autism spectrum disorder (ASD). Here, we review the findings and limitations of recent efforts to identify relatively "autism-specific" genes, efforts which focus on rare variants of large effect size that are thought to account for the observed phenotypes. We present a divergent interpretation of published evidence; discuss practical and theoretical issues related to studying the relationships between rare, large-effect deleterious variants and neurodevelopmental phenotypes; and describe potential future directions of this research. We argue that there is currently insufficient evidence to establish meaningful ASD specificity of any genes based on large-effect rare-variant data.

Abbreviations: 2LL, 2 × logarithm of the likelihood; Diff − 2LL, 2 × difference in log-likelihood between the model and the full model; NA, not applicable.

[a] The 95% CIs are 2-sided CIs. Variances are based on the tetrachoric correlations. The unadjusted tetrachoric correlation (SD) was estimated to 0.87 (0.08) and 0.40 (0.10) for monozygotic and dizygotic twins; 0.41 (0.01) for full siblings; 0.22 (0.03) and 0.17 (0.04) for maternal and paternal half siblings.

[b] All models adjusted for sex and birth cohort. The genetic terms for each model are shown in each row, which include additive genetic effect (A; inherited additive effects of different alleles), shared environmental factors (C; nongenetic influences contributing to similarity within sibling pairs), nonadditive (dominant) genetic factors (D; interaction effects between alleles at the same locus), and nonshared environmental factors (E; making siblings dissimilar).

[c] *P* value for testing the hypothesis: the parameters not in the model but in the full model are all equal to 0.

Attention-deficit/hyperactivity disorder and risk for psychiatric and neurodevelopmental disorders in siblings

Original Article

Elina Jokiranta-Olkoniemi[1], Keely Cheslack-Postava[2], Petteri Joelsson[1], Auli Suominen[1], Alan S. Brown[2,3] and Andre Sourander[1,2]

Methods. Every child born in Finland in 1991–2005 and diagnosed with ADHD in 1995–2011 were identified from national registers. Each case was matched with four controls on sex, place, and date of birth. The full siblings of the cases and controls were born in 1981–2007 and diagnosed in 1981–2013. In total, 7369 cases with 12 565 siblings and 23 181 controls with 42 753 siblings were included in the analyses conducted using generalized estimating equations.

New guidance to seekers of autism biomarkers: an update from studies of identical twins

John N. Constantino*

Abstract

Background: The autism spectrum disorders (ASD) are common neuropsychiatric conditions of childhood for which the vast proportion of population risk is attributable to inheritance, and for which there exist few if any replicated biomarkers.

Main body: This commentary summarizes a set of recent studies involving identical (monozygotic, MZ) twins which, taken together, have significant implications for the search for biomarkers of inherited susceptibility to autism. A first is that variation-in-severity of the condition (above the threshold for clinical diagnosis) appears more strongly influenced by stochastic/non-shared environmental influences than by heredity. Second is that there exist disparate early behavioral predictors of the familial recurrence of autism, which are themselves strongly genetically influenced but largely independent from one another. The nature of these postnatal predictors is that they are trait-like, continuously distributed in the general population, and largely independent from variation in general cognition, thereby reflecting a developmental substructure for familial autism. A corollary of these findings is that autism may arise as a developmental *consequence* of an allostatic load of earlier-occurring liabilities, indexed by early behavioral endophenotypes, in varying permutations and combinations. The clinical threshold can be viewed as a "tipping point" at which stochastic influences and/or other non-shared environmental influences assert much stronger influence on variation-in-severity (a) than do the genetic factors which contributed to the condition in the first place, and (b) than is observed in typical development.

Conclusion: Biomarkers identified on the basis of association with clinical symptom severity in ASD may reflect *effects* rather than *causes* of autism. The search for biomarkers of pathogenesis may benefit from a greater focus on traits that predict autism recurrence, among both clinical and general populations. In case–control studies, salient developmental liabilities should be systematically measured in both cases and controls, to avoid the erosion in statistical power (i.e., to detect differences) that can occur if control subjects carry sub-clinical aggregations of the same unmeasured traits that exert causal influences on the development of autism.

Inherited Risk for Autism Through Maternal and Paternal Lineage

Dan Bai, Natasha Marrus, Benjamin Hon Kei Yip, Abraham Reichenberg, John N. Constantino, and Sven Sandin

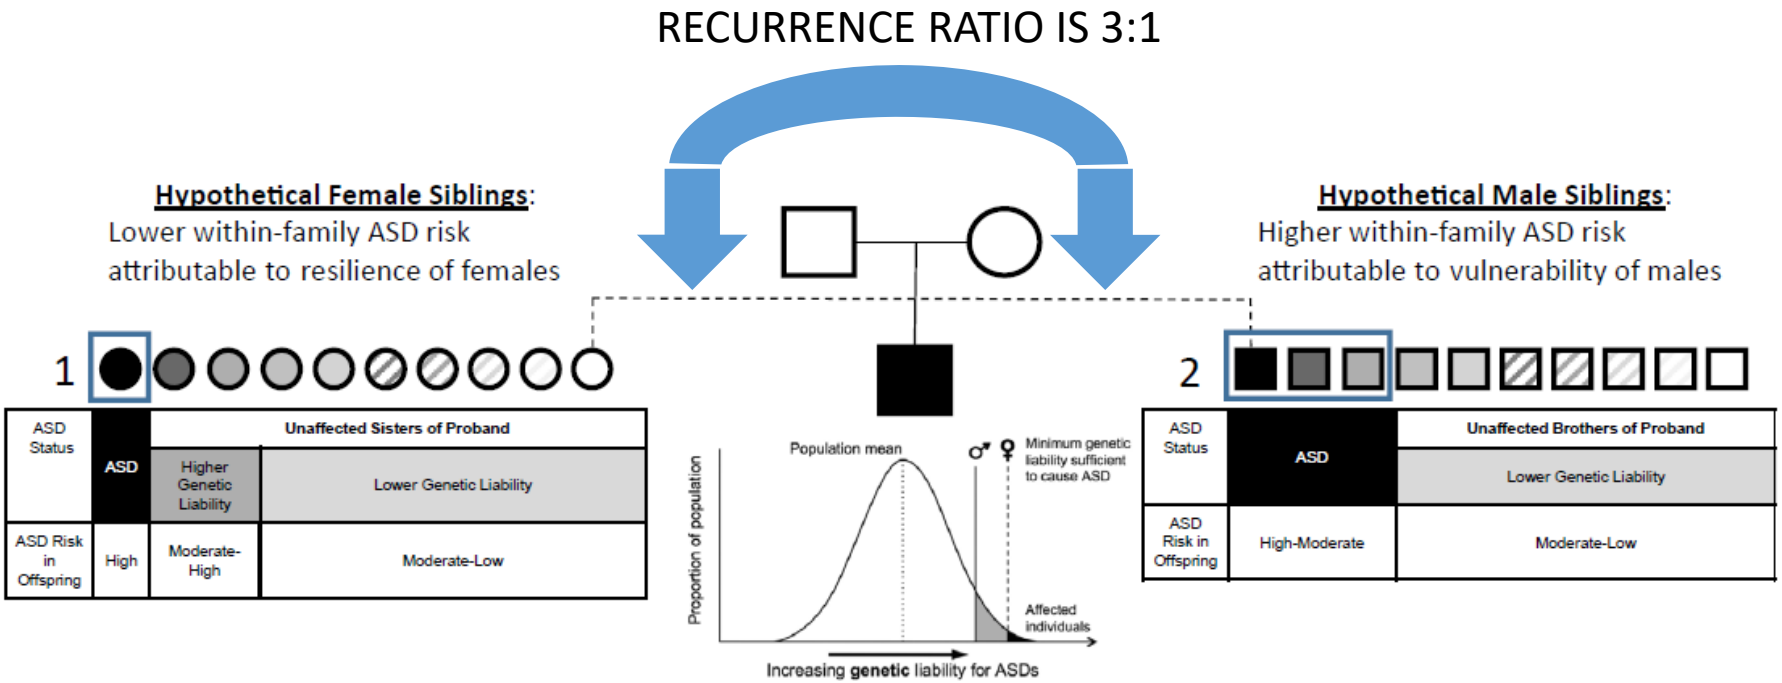

Figure 1. The expected autism spectrum disorder (ASD) liability under the female protective effect. Example: an individual has ASD and, hypothetically, he has 10 sisters (left panel, circles) and 10 brothers (right panel, squares). Under a female protective effect, 1) only the sisters with very high genetic liability will be diagnosed with ASD; and 2) for the brothers, there will be more diagnosed cases of ASD: in this example, a 3:1 male-to-female ratio. In the next generation (not shown in the pedigree), because it is more likely that undiagnosed sisters carry a moderate-to-high genetic liability, the relative risk of ASD among offspring to the undiagnosed siblings is expected to be higher among those to the sisters than among those to the brothers.

Biological Psychiatry

Table 2. Relative Risks for ASD Among Participants With ASD-Affected Uncle(s)/Aunt(s) Compared With Participants With Uncle(s)/Aunt(s) Free From ASD Diagnosis

	Person-Years of Follow-up		Rates of ASD per 100,000 Person-Years		Relative Risk (95% CI)[a]		
Exposure	Exposed	Unexposed	Exposed	Unexposed	Crude	Adjusted 1[b]	Adjusted 2[c]
Maternal Lineage							
Uncle(s) affected by ASD	19,662	6,675,534	401.79	151.07	3.22 (2.54–3.91)	2.75 (2.15–3.36)	1.92 (1.49–2.37)
Aunt(s) affected by ASD	9984	6,337,615	340.54	152.71	2.73 (1.88–3.73)	2.36 (1.62–3.21)	1.73 (1.19–2.35)
Uncle(s)/aunt(s) affected by ASD	29,646	13,013,149	381.16	151.87	3.05 (2.52–3.64)	2.62 (2.17–3.14)	1.88 (1.54–2.26)
Paternal Lineage							
Uncle(s) affected by ASD	13,274	6,723,265	301.35	153.23	2.39 (1.72–3.13)	2.09 (1.50–2.74)	1.63 (1.16–2.16)
Aunt(s) affected by ASD	7342	6,292,408	190.68	151.99	1.52 (0.79–2.30)	1.33 (0.69–2.01)	1.07 (0.56–1.63)
Uncle(s)/aunt(s) affected by ASD	20,616	13,015,674	261.94	152.63	2.08 (1.53–2.67)	1.82 (1.32–2.34)	1.44 (1.05–1.86)

"Affected by ASD" refers to an individual with a clinical diagnosis of ASD.
ASD, autism spectrum disorder; CI, confidence interval.
[a]Bootstrapped 95% CI: 2.5%–97.5% percentiles of estimates from 1000 bootstrapped samples.
[b]Adjusted for the birth year of the participant, the mother, and the uncle/aunt.
[c]Adjusted for covariates in Adjusted 1 and any mental illness (yes/no) of the mother and the uncle/aunt.

First epidemiologic estimate of risk to second generation offspring:

For sisters of an ASD-affected individual, risk of autism = 2-3 x population risk (2-5%)
And not significantly elevated over that for the offspring of brothers of an ASD proband

4. Shift Happens

Background genetic variation within the normal range shifts the “starting point” for the deleterious effects of some (not all) mutations

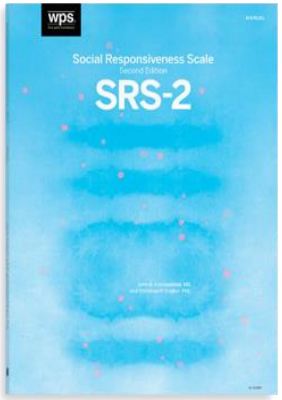
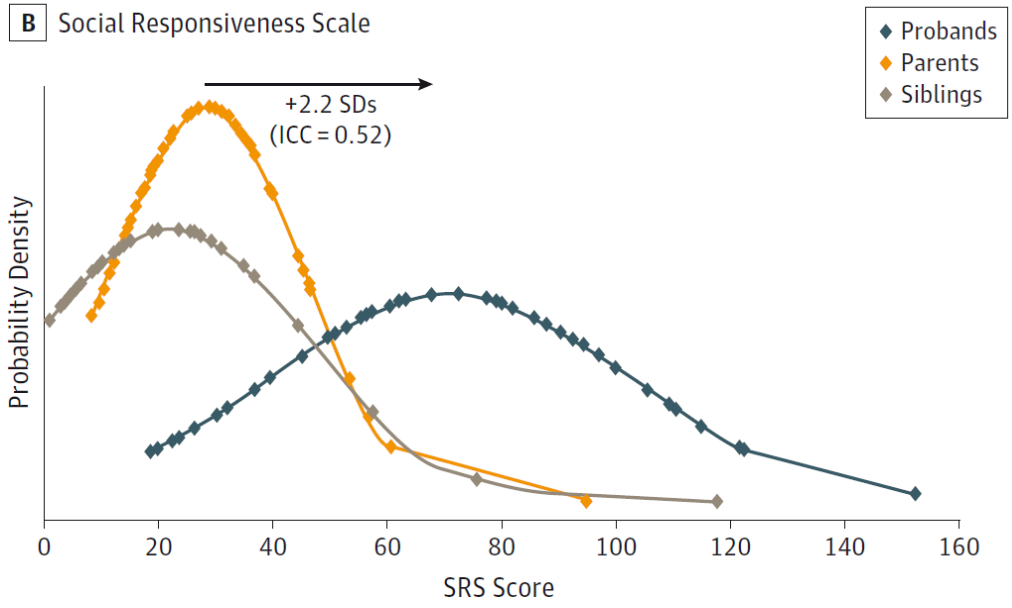
Shift happens: family background influences clinical variability in genetic neurodevelopmental disorders

Brenda Finucane, MS, LGC[1], Thomas D. Challman, MD, FAAP[1], Christa Lese Martin, PhD, FACMG[1] and David H. Ledbetter, PhD, FACMG[1]





Conclusions

- The strong family genetic liability to ***autism*** operates via multiple independent liabilities, permutations and combinations of which give rise to autism; in this sense autism is “fractionable” before it develops BUT NOT AFTER
- Autism ***severity*** is strongly influenced by stochastic influences / non-shared environmental effects—this is true above, but not below, the clinical threshold
- If the components of the developmental sub structure for autism are not measured among CONTROL subjects (or as indexed by parental background traits in “shift” studies), expect erosion in ***statistical power*** to identify a genotype-phenotype association (or any biomarker association related to cause of ASD
- Framing the ASD sex bias as a function of ***male sensitivity*** rather than female protection has major implications for the design of future studies (including cell, organoid, rodent) of the effects of sex on ASD
- New approach to ***early behavioral intervention***?: “nudging” endophenotypic liabilities into the safe/normative range before autism develops
    - Social visual disengagement
    - Inattention
    - Motor coordination deficits (cerebellar learning)
    - ? Tactile sensitivity

* Includes nine sites (Arizona, Arkansas, Colorado, Georgia, Maryland, Minnesota, New Jersey, North Carolina, and Tennessee) that had intellectual ability data available for ≥70 of children who met the ASD case definition (n = 3,714).

Maenner et al. MMWR 2020

Prevalence estimates were approximately identical for non-Hispanic white and non-Hispanic black children (18.5 and 18.3, per thousand, respectively)

Among children with ASD for whom data on intellectual or cognitive functioning were available, 33% were classified as having intellectual disability (intelligence quotient [IQ] ≤70); this percentage was higher among black and Hispanic than white children (47%, 36%, and 27%, respectively).

Black children with ASD were less likely to have a first evaluation by age 36 months than were white children with ASD (40% versus 45%).

Black children with IQ ≤70 had a later median age at ASD diagnosis than white children with IQ ≤70 (48 months versus 42 months).

Structural Racism and Autism

Sarabeth Broder-Fingert, MD, MPH,[a] Camilla Mateo, MD, MPH,[b] Katherine E. Zuckerman, MD, MPH[c]

- **We believe these data shed light on structural racism as a driver of inequity for children with ASD.**
- **31.3% of parents cited availability of professionals as a barrier to diagnosis.**
  - Workforce capacity has long been a major challenge in the field of ASD.
  - This issue may be compounded for AA families who may be more likely than white families to live in areas with few ASD diagnostic specialists and also be more likely to rely on Medicaid.
  - Medicaid may aggravate inequities because low rates of Medicaid reimbursement for diagnostic services can create challenges to supporting and maintaining a workforce.
- **Thus, AA families may be suffering from a lack of available workforce related to <u>where they live</u> (as a result of structural racism in housing policy), whereas clinics serving these communities may be <u>unable to expand capacity</u> (because of structural racism in Medicaid reimbursement rates).**
- **These issues are likely exacerbated by additional issues on the provider level including a lack of cultural humility and workforce diversity. Notably, a recent workforce survey showed that only 2% of developmental-behavioral or neurodevelopmental pediatricians are AA.**

Infant viewing of social scenes is under genetic control and is atypical in autism

John N. Constantino[1,2,3], Stefanie Kennon-McGill[1], Claire Weichselbaum[1], Natasha Marrus[1,3], Alyzeh Haider[1], Anne L. Glowinski[1], Scott Gillespie[4], Cheryl Klaiman[5,6], Ami Klin[5,6,7] & Warren Jones[5,6,7]

Table 1 Falconer's heritability and twin-twin correlations for two behavioral predictors of ASD recurrence (Attention Problems and variation in Motor Coordination) and autism-related variation in reciprocal social behavior in the fourth year of life

	Attention problem (CBCL)	Motor coordination (Little DCDQ)	Reciprocal social behavior (SRS-2)
MZM twin-twin correlation	.527	.937	.784
DZM twin-twin correlation	−.013	.734	.327
MZF twin-twin correlation	.583	.898	.913
DZF twin-twin correlation	−.081	.625	.352
Heritability (males)	.53*	.41	.91
Heritability (females)	.58*	.55	.91*

The analysis excluded opposite sex twin pairs and pairs with uncertain zygosity; they are derived from 66 MZ pairs (34 male-male and 32 female-female) and 58 DZ pairs (30 male-male, 28 female-female) with complete data for these three variables
*For heritability estimate >1, MZ concordance rate is used by convention
MZM monozygotic male
DZM dizygotic male
MZF monozygotic female
DZF dizygotic female
CBCL child behavior checklist
Little DCDQ developmental coordination disorder questionnaire
SRS-2 social responsiveness scale, 36 months

Table 2 Matrix depicting within-individual correlations (Pearson's *r*) between autism recurrence predictors in 174 general population twins (one twin selected at random from each pair)

	Attentional impairment	QAT-p	Motor coord	SRS 36 months	SRS 48 months
Attentional impairment	1				
QAT-p	.20	1			
Motor coordination	−.20	−.16	1		
SRS-2 (36 months)	.46	.38	−.36	1	
SRS-2 (48 months., $n = 160$)	.48	.28	−.35	.71	1

All correlations above 0.29 were statistically significant at $p < .01$; none of the bivariate associations between BPARs reached this threshold. Bivariate cross-twin cross-trait correlations encompassing attentional impairment, QAT-p, and motor coordination were uniformly non-statistically significant
